

Hashing (continued)

Double Hashing

Several keys hash to same index → **clustering** around that location ...*why bad???*

One strategy is to use **2nd hash function** to try different spots when there's a collision

$h_1(\text{key})$ determines which index to try first
 $h_2(\text{key})$ determines how far away from index to try next

Ex: $h_1(\text{key}) = 200$ and $\text{data}[200]$ is already taken
 $h_2(\text{key}) = 8$ so next try $\text{data}[208]$, $\text{data}[216]$, $\text{data}[224]$, etc.

Warning!

- **Make sure you still wrap around the array**
- **Don't come back to original index without having tried other available positions**

Make CAPACITY be a prime number

$h_1(\text{key}) = \text{key} \% \text{CAPACITY}$

$h_2(\text{key}) = 1 + (\text{key} \% (\text{CAPACITY} - 2))$

Chained Hashing

- Each slot in hash table can hold **more than one entry**
- That is, each slot is **pointer to a linked list** (not a key value)

Average Search Time for Hashing

Load factor $f = \# \text{ entries} / \text{CAPACITY}$ (can be > 1 for open-address hashing)

Open Addressing with Linear Probing

avg. # table elements examined = $0.5 * (1 + (1 / (1 - f)))$

Open Addressing with Double Hashing

avg. # table elements examined = $-\ln(1 - f) / f$

Chained Hashing

avg. # table elements examined = $1 + (f / 2)$
